Illustration 14.17 illustrate a constructor defined inside the private visibility.

```
#include<iostream>
using namespace std;
class X
 {
          int num;
          X()
    {
          num=k=0;
     }
  public:
  int k;
 };
int main()
{
X x;   // The constructor of X cannot accessed by main() because main() is a
          //non member function
          //and the compiler throws error message       [Error] 'X::X()' is private
return 0;
}
```

14.12.1 Functions of constructor

As we know now that the constructor is a special initialization member function of a class that is called automatically whenever an instance of a class is declared or created. The main function of the constructor is

1) To allocate memory space to the object and

2) To initialize the data member of the class object

There is an alternate way to initialize the class objects but in that case we have to explicitly call the member function.
